Abstract

Sleep slow waves are known to participate in memory consolidation, yet slow waves occurring under anesthetized states present no positive effects on memory. Here, we shed light onto this paradox, based on a combination of extracellular recordings \textit{in vivo}, \textit{in vitro}, and computational models. We find two types of slow waves, based on analyzing the temporal patterns of successive slow-wave events. The first type of slow waves is seen during sleep, while the second type prevails in anesthetized states. Network models of spiking neurons predict that the two slow wave types emerge due to a different gain on inhibitory vs excitatory cells and that different levels of spike-frequency adaptation in excitatory cells can account for dynamical distinctions between the two types. This prediction was tested \textit{in vitro} by varying adaptation strength using an agonist of acetylcholine receptors, which demonstrated a neuromodulatory switch between the two types of slow waves. Finally, we show that the first type of slow-wave dynamics is more sensitive to external stimuli, which
can explain how slow waves in sleep and anesthesia differentially affect memory consolidation, as well as provide a link between slow-wave dynamics and memory diseases.

**Introduction**

In both natural sleep and anesthesia, cortical dynamics are characterized by slow, irregular oscillations (<1 Hz) [Steriade et al., 1993]. However, certain cognitive processes, such as those involved in memory formation [Wilson and McNaughton, 1994, Mehta, 2007, Peyrache et al., 2009], are specific to deep sleep (also known as Slow-Wave Sleep, SWS), but not to anesthesia. While contrasts between sleep and anesthesia are relatively well-studied at the whole-brain scale in terms of interactions between brain regions [Battaglia et al., 2004, Brown et al., 2010, Akeju and Brown, 2017, Urbain et al., 2019], any underlying differences in the microscopic dynamics of cortical neural networks and their potential mechanisms remain to be identified. In fact, while anesthesia and sleep appear to produce similar collective dynamics, it is still unknown whether any differences exist in the correlation structure of network dynamics between the two states, and how they may affect the system’s ability to encode and remember stimuli.

At the neural population level, in both sleep and anesthesia, slow oscillations emerge from the alternation between transients of high neural firing (UP states) and transients of near silence (DOWN states) [Steriade et al., 1993]. While anesthesia can present very regular UP and DOWN states [Niedermeyer et al., 1999, Bruhn et al., 2000, Deco et al., 2009], in obvious contrast with the irregular patterns observed during sleep slow waves [Akeju and Brown, 2017], irregular regimes also exist under anesthesia for certain anesthetics and depth [Deco et al., 2009, Jerog et al., 2017, Tort-Colet et al., 2019], that may appear similar to dynamics observed in natural sleep. Additionally, UP-DOWN state activity has been obtained in slice preparations in vitro [Sanchez-Vives and McCormick, 2000]. Due to their general similarity in collective dynamics, slices and anesthesia, where direct pharmacological manipulation is possible, have often been used as models of natural sleep, paving the way to investigating mechanisms underlying UP-DOWN state activity.

Nevertheless, sleep and anesthesia present different levels of neuromodulation, known to affect the electrophysiological properties of neurons and how they respond to external inputs. In particular, as anesthesia is characterized by lower concentrations of acetylcholine (ACh) compared to sleep [Jones, 2003, McCormick, 1992], resulting in enhancement of spike-frequency adaptation driven by K+ channels [McCormick and Williamson, 1989]. Following the increasing electrophysiological detail available on single neuron dynamics, computational models of spiking neurons have been employed to simulate
spike-frequency adaptation and account for UP-DOWN state dynamics [Compte et al., 2003, Mattia and Sanchez-Vives, 2012, Capone et al., 2017]. Indeed, comparison of models with neural recordings in anesthesia has recently uncovered a mechanistic interpretation for the emergence of UP and DOWN states, where background noise and neuromodulation, which control spike-frequency adaptation, can account for the transitions between UP states and DOWN states [Jercog et al., 2017]. While background noise is able to trigger a transition from a DOWN to UP state, spike-frequency adaptation on excitatory cells produces a self-inhibition that, destabilizing the UP state, causes a reset to the DOWN state [Mattia and Sanchez-Vives, 2012]. However, it is plausible that subtle mechanistic particularities at the microscopic scale could be expressed as differences in the collective network dynamics that underlie distinct computational properties of sleep and anesthesia.

In the present paper, we uncover fundamental differences in correlation structure of slow waves during sleep and anesthesia, that can explain the different capacity for information encoding between the two states. We investigate computational models to unveil plausible mechanisms underlying these differences. These mechanisms are subsequently tested in in vitro preparations displaying UP-DOWN state dynamics, where pharmacological manipulation is possible. In summary, we demonstrate ways in which slow-wave dynamics differ between anesthesia and slow-wave sleep, robustly across different anesthetics, brain regions, and species, and propose possible mechanisms and functional consequences of these differences.

Methods

Neural recordings

Human temporal cortex in deep sleep

The data was recorded with intra-cranial multi-electrode array recordings of 92 neurons in the temporal cortex of an epileptic patient, the same data-set used by [Peyrache et al., 2012, Dehghani et al., 2016, Teleńczuk et al., 2017, Le Van Quyen et al., 2016, Nghiem et al., 2018]. The record of interest spans across approximately 12 hours, including periods of wakefulness as well as several stages of sleep. Recordings were performed in layer II/III of the middle temporal gyrus, in an epileptic patient (found to be far from the epileptic focus and not registering epileptic activity outside of generalized seizures). Data acquisition in that region was enabled by implanting a multi-electrode array, of dimensions 1 mm in thickness and 4x4 mm in area, with 96 micro-electrodes separated by 400 µm spacings. The array was implanted to localize seizure foci. A 30-kHz sampling frequency was employed for recording. Switches in brain state (wakefulness, SWS,
REM, seizure, ...) throughout the recording were noted from the patient’s behavioural and physiological parameters, yielding one hour of SWS on which our analyses were focused. Using spike sorting methods on the obtained data, 92 neurons have been identified. Analysis of the spike waveforms for each of these neurons allowed their classification as putative excitatory (E) and inhibitory (I) neurons. Using the spike times of each neuron, cross-correlograms for all pairs of neurons were also computed to determine whether each neuron’s spikes had an excitatory (positive correlation) or an inhibitory (negative correlation) effect on other neurons through putative monosynaptic connections. It should be noted that neurons found to be excitatory exactly corresponded to those classified as regular spiking (RS), while all inhibitory neurons were also fast spiking (FS). We only retained neurons spiking throughout the recording for our analyses, amounting to 71 neurons of which 21 were I neurons. Spikes were binned into 1 ms wide time bins for all subsequent analyses. A statistical analysis of UP DOWN states duration is presented in Fig.SS1 (panels A-D and E left).

**Monkey premotor cortex in deep sleep**

Spiking activity (the same data-set as used in [Dehghani et al., 2016, Teleńczuk et al., 2017, Le Van Quyen et al., 2016, Nghiem et al., 2018]) in layer III/IV of the premotor cortex of a macaque monkey was recorded by multi-electrode arrays throughout a night. A 10-kHz sampling frequency was employed for recording. Classification of brain states, for extraction of SWS periods, was performed by visual inspection of the Local Field Potential (LFP), over time periods of 5 s, by identifying as SWS periods presenting large-amplitude oscillations in the 1-2 Hz frequency range [Nghiem et al., 2018], of which 141 spiked throughout the whole recording, yielding three hours of SWS data for subsequent analyses. All analyses in this work were performed with spikes binned into 1 ms time bins.

**Rat prefrontal cortex in deep sleep**

The analysis was performed on the dataset of single unit activities previously employed in [Peyrache et al., 2009, Benchenane et al., 2010, Tavoni et al., 2017]. Here we provide a short description only. Five Long-Evans male rats were chronically implanted with tetrodes in the prelimbic subdivision of the medial prefrontal cortex and in the intermediate-ventral hippocampus. Tetrodes in the hippocampus were used for identification of non-REM sleep periods, through a clustering analysis of the LFP power within the cortical delta band (1 – 4Hz), hippocampal theta (5 – 10Hz) and cortical spindles (10 – 20Hz) together with estimates of the speed of head movements. Tetrodes in the cortex were used for single unit recording. Spike sorting has been performed using KlustaKwik [Kadir et al., 2014].
Recordings were organized in daily sessions, where the rat undergoes a first sleeping epoch, then a task learning epoch, in which the rat performs an attentional set shift task on a Y shaped maze, and finally a second sleeping epoch, each epoch lasting 30 mins. In general, the neurons recorded differed from a session to another, with the number of cells recorded per session varying between 10 and 50. For the analysis of up/down state duration, the results from all session from the same rat were joined together, but pre-task and post-task sleep were kept separated.

Monkey primary visual cortex under sufentanil anesthesia

The data-set may be found at [Kohn and Smith, 2016], as described in [Smith and Kohn, 2008]. Four adult macaque monkeys were recorded using a total of six multielectrode arrays implanted in the primary visual cortex. Sufentanil (4-18 µg/kg/hr) was used for anesthesia. Recordings were obtained while animals viewed a uniform gray screen, over periods of between 20 and 30 minutes long. Spontaneous spiking activity from 70–100 neurons was recorded and spike-sorted for each array. Spikes were binned into 1 ms time bins for subsequent analyses. A statistical analysis of UP DOWN states duration is presented in Fig.S1E right.

Rat primary visual cortex under ketamine anesthesia

7 adult male Wistar rats weighting 211 ± 58 g (mean ± s.d.) were anesthetized via intraperitoneal injection of ketamine (120 mg/kg) and medetomidine (0.5 mg/kg). Atropine (0.05 mg/kg) was injected subcutaneously to prevent respiratory secretions. Rectal temperature was maintained at 37°C. A craniotomy was performed to access the primary visual (V1) cortex (7.3 mm AP, 3.5 mm ML) of the right hemisphere [Paxinos and Watson, 2004].

Recordings of cortical activity under anesthesia were obtained with a 16-channel silicon probe (1 shank with 16 linearly spaced sites at 100µm increments with impedances of 0.6–1 MΩ at 1kHz (NeuroNexus Technologies, Ann Arbor, MI)) introduced perpendicularly in V1 under visual guidance until the most superficial recording site was aligned with the cortical surface. Signals were amplified (Multi Channel Systems), digitized at 10kHz and acquired with a CED acquisition board and Spike 2 software (Cambridge Electronic Design, UK). Recordings had an average length of 951.46 +/-219.30 seconds. UP and DOWN states were singled out by thresholding the multi-unit activity (MUA), which was estimated as the power of the Fourier components at high frequencies (200-1500 Hz) of the extracellular recordings (LFP) [Reig et al., 2010, Sanchez-Vives et al., 2010, Ruiz-Mejias et al., 2011, Mattia et al., 2016, Tort-Colet et al., 2019]. For each experiment, we selected the channel with maximum MUA during the Up state, whose location in depth corresponds to cortical layer 5 [Tort-Colet et al., 2019, Mattia et al., 2016].
All experiments were supervised and approved by the local Ethics Committee and were carried out in accordance with the present laws of animal care, EU guidelines on protection of vertebrates used for experimentation (Strasbourg 3/18/1986) and the local law of animal care established by the Generalitat of Catalonia (Decree 214/97, 20 July).

Mouse entorhinal cortex slice preparations

We prepared brain slices exhibiting spontaneous slow waves in entorhinal cortex using a method described in [Tahvildari et al., 2012]. The mice were of wild-type (C57BL/6J) and 11-18 days old.

The dissection and slice cutting were performed in an ice-cold cutting solution containing (in mM): 85 NaCl, 75 sucrose, 3 KCl, 26 NaHCO$_3$, 1.25 NaH$_2$PO$_4$, 3.5 MgSO$_4$, 0.5 CaCl$_2$, 10 glucose, 3 myo-inositol, 3 Na-pyruvate, 0.5 L-ascorbic acid and aerated with 95% O$_2$ and 5% CO$_2$. Lower concentrations of Na$^+$ and Ca$^{2+}$, and a higher concentration of Mg$^{2+}$ in the cutting solution, compared to a standard ACSF, are applied to minimize neuronal damage during cutting.

We cut slices at a 15° angle off the horizontal plane with the thickness of 310 µm. After cutting, slices were placed in a cutting solution at temperature of 35°C for 30 min.

The slices were then kept at room temperature in a storing solution containing (in mM): 126 NaCl, 3 KCl, 26 NaHCO$_3$, 1.25 NaH$_2$PO$_4$, 2 MgSO$_4$, 2 CaCl$_2$, 10 glucose, 3 myo-inositol, 3 Na-pyruvate, 0.5 L-ascorbic acid.

For recording, the slices were transferred to a submersion chamber and placed between nylon nets. The well oxygenated recording solution was flowing with the speed of 4ml/min. The recording solution was similar to storing solution, with only CaCl$_2$ and MgSO$_4$ concentrations reduced to 1.2 and 1 mM respectively. The extracellular field was recorded with glass electrodes with a resistance of 2-3 $M\Omega$. The electrode was placed in layer 2/3 of the entorhinal cortex.

Electrophysiological data was acquired using the ELPHY software [Sadoc, 2014]. The multi-unit activity was obtained from the signal by calculating the time-averaged power of the signal in the frequency range (0.3 - 2 kHz).

Spiking network model

We consider a population of $N = 10^4$ neurons connected over a random directed network with probability of connection $p = 5\%$. We consider excitatory and inhibitory neurons, with 20% inhibitory neurons. The dynamics of each of the two types of neurons is based on the adaptive integrate and fire model, described by the following equations

$$ c_m \frac{dv_i}{dt} = g_L (E_L - v_i) + g_L k_a e^{\frac{v_i - v_{thr}}{k_a}} - w_i + I_{syn} + \sigma \xi_i(t) $$

(1)
\[
\frac{dw_i}{dt} = -\frac{w_i}{\tau_w} + b \sum_{t_{sp}(i)} \delta(t - t_{sp}(i)) + a(v_i - E_L),
\]

where \(c_m\) is the membrane capacity, \(v_i\) is the voltage of neuron \(i\) and whenever \(v_i > v_{\text{thr}}\) at time \(t_{sp}(i)\), \(v_i\) is reset to the resting voltage \(v_{\text{rest}}\) and fixed to that value for a refractory time \(\tau_r\). The exponential term mimics activation of sodium channels and parameter \(k_a\) describes its sharpness. Inhibitory neurons are modeled according to physiological insights [Destexhe, 2009] as fast spiking FS neurons with no adaptation while the strength \(b\) of spike-frequency adaptation in excitatory regular spiking RS neurons is varied. The synaptic current \(I_{\text{syn}}\) received by neuron \(i\) is the result of the spiking activity of all pre-synaptic neurons \(j \in \text{pre}(i)\) of neuron \(i\). This current can be decomposed in the result received from excitatory E and inhibitory I pre-synaptic spikes \(I_{\text{syn}} = (E_e - v_i)I_{\text{syn}}^e + (E_I - v_i)I_{\text{syn}}^I\). Notice that we consider voltage dependent conductances. Finally, we model \(I_{\text{syn}}^x\) as a decaying exponential function that takes kicks of amount \(Q_x\) at each pre-synaptic spike, i.e.:

\[
I_{\text{syn}}^x(t) = Q_x \sum_{\text{exc-pre}} \delta(t - t_{sp}(i))e^{-\frac{t - t_{sp}(i)}{\tau_x}},
\]

where \(x\) represents the population type \((x = E, I)\), \(\tau_x\) is the synaptic decay time scale and \(Q_x\) the quantal conductance. We will have the same equation with \(E \rightarrow I\) for inhibitory neurons. Every neuron \(i\) receives an identically distributed white noise \(\xi(t)\) of zero mean and instantaneously decaying autocorrelation \(\langle \xi_i \rangle = 0\), \(\langle \xi_i(t)\xi_j(t + s) \rangle = \delta_{i,j}\delta(t - s)\). The noise amplitude \(\sigma\) is a piecewise constant function of time, i.e. its value stays constant for a time window of length \(T\) and is extracted from a uniform distribution of amplitude \(\Delta\). In our simulations \(\Delta\) varies and we use \(T = 100s\), in accordance to the observed variability of UP-DOWN states duration during sleep.

A transient of 1s after simulation onset is discarded from all analyses. An example of the dynamics of this system is reported in Fig.S2A and statistics of UP DOWN states durations obtained with the model are shown in Fig.S2B-E.

To deliver a stimulus to the network, each neuron receives an external Poissonian spike train of frequency 0.05 Hz for a duration of 50 ms. Stimuli are delivered halfway through the first UP state after the discarded transient. To directly compare network dynamics in the presence and absence of a stimulus, the network connectivity matrix and initial conditions are the same in both simulations, such that dynamics before the stimulus onset are identical, and differences in dynamics following the onset are only due to the stimulation. The cumulative spike count is computed in each case, at each point in time. The normalized distance between the spike counts with and without stimulus is defined by:

\[
D = \frac{|s' - s|}{<s>},
\]

where \(s'\) and \(s\) are the cumulative spike counts with and without stimulus, respectively.
where \( s \) is the spike count for the unstimulated network, \( s' \) is the spike count for the stimulated network, and \(< \cdot >\) denotes time averaging. Each simulation lasts 30s, and the procedure is repeated 50 times, each time with different connectivity realization and initial condition set. In Fig. 4 of the main paper we report the average value of \( D \) over different realizations, together with its standard deviation.

**UP DOWN state detection and statistics**

The method to detect UP states ([Renart et al., 2010], Section 1.3.3. of Suppl Mat.) considers the sum of all cells' spike trains (bin size of 1 ms), \( K(t) = \sum_i \sigma_i(t) \). The instantaneous population activity \( m(t) \) is the smoothed \( K(t) \), by convolution with a Gaussian density with width \( \alpha = 10 \text{ ms} \). Any period of time for which the instantaneous population activity \( m(t) > \theta \max(m(t)) \) is considered an UP state, where the threshold \( \theta \) was chosen in terms of the sparseness and non-stationarity of each data-set. \( \theta = 0.2 \) was for most data-sets, as in [Renart et al., 2010], except human SWS and the spiking model, where \( \theta = 0.02 \), and slice preparations, for which \( \theta = 0.5 \). Note that the threshold was chosen to be low due to UP states themselves being relatively quiescent in this data-set (human temporal cortex, layer 2-3, recorded with multi-electrode array). Indeed, as estimated from the spikes of the recorded 10^2 neurons the firing rate is low even in the UP state. While UP states are usually visible by eye (Fig. 1A), a low threshold is needed to discriminate UP states from DOWN states. States lasting less than 50 ms were excluded by considering it a part of the previous sufficiently long state. States longer than 5 s are discarded from the analysis. Parameters used for detection were determined by visual inspection of the detection quality. It was also verified that slight variation of these parameters did not qualitatively affect the results presented in this work (Fig. S3), suggesting observed effects are robust rather than artefacts of the detection method.

This method was tested against a different method where UP and DOWN states were singled out by setting a minimum state duration of 80ms and a threshold in \log(MUA) \) values at 1/3 of the interval between the peaks of the bimodal distribution of \log(MUA) \) corresponding to the Up and Down states. The algorithm, adapted from [Mattia and Sanchez-Vives, 2012, Ruiz- Mejias et al., 2011, Tort-Colet et al., 2018, Tort-Colet et al., 2019], yielded qualitatively identical results.

The Pearson correlation was then employed to evaluate how strong and significant the correlation between UP state and previous DOWN state durations are. As a further test for significance, the information present in time structure was destroyed by shuffling all DOWN state durations, while leaving UP state durations in their empirical order, and computing the Pearson correlation again. This procedure is repeated 1,000 times, and the mean and standard deviation of the Pearson correlations obtained each time are
calculated. The interval contained within two standard deviations above and below the mean of correlations obtained from shuffled is considered as a confidence interval. Indeed, a correlation well outside of this interval is highly unlikely to have been produced by a chance arrangement of UP and DOWN states in time, given the empirical distribution of their durations, and implies a non-trivial structure in time.

This procedure is used to evaluate the correlation between each UP state and the DOWN states surrounding it, \( C(D_{n+k}, U_n) \), with \( k = 0 \) denoting the previous DOWN state to the considered UP state, negative \( k \) denoting previous DOWN states more distant in time, and positive \( k \) denoting DOWN states following the UP state of interest.

The scripts used for UP and DOWN state detection and analysis can be found at https://github.com/tnghiem/up-down-analysis.

Results

Two types of slow waves found in anesthesia and natural sleep

To compare with previous anesthesia results [Jercog et al., 2017, Deco et al., 2009], we consider the activity of a population of \( 10^2 \) neurons recorded from the temporal cortex of a human patient (Fig. 1A-C) during sleep. The dynamics are characterized by slow waves, as evident from Local Field Potentials (LFP) associated with an alternation of low (DOWN) and high (UP) activity periods, as visible in spiking activity. In all our analyses UP and DOWN states are defined based on neuron spiking activity (see Methods). The time duration of both DOWN and UP states are variable, following an exponential, long-tailed distribution (see Methods), similar to what has been reported for anesthesia recordings [Jercog et al., 2017].

While the distributions of UP and DOWN state durations found in sleep and anesthesia are similar, surprisingly, the temporal distribution of UP and DOWN state durations is different. In anesthesia, DOWN state and next UP state durations are positively correlated, in other words long DOWN states are followed by long UP states, as shown in previous work [Jercog et al., 2017]. However, we find that in sleep, DOWN state and next UP state durations are negatively correlated, as long DOWN states are followed by short UP states (Fig. 1B). Indeed, during sleep, while long UP states can occur after short DOWN states, UP states following long DOWN states are consistently short.

Because a difference in temporal correlation was found for adjacent UP and DOWN epochs between sleep and anesthesia, we next explored whether the network retains a memory of previous epochs further in time. To this end, correlations between the \( n \)-th DOWN state and the \( (n+k) \)-th UP state duration were explored. Here, \( k = 0 \) denotes the UP state following the \( n \)th DOWN state, as studied so far, while \( k = -1 \) denotes the UP state preceding the \( n \)th DOWN state in time. As shown in Fig.1C, the length of time...
Figure 1: Different types of slow waves during sleep and anesthesia, across species, brain regions, and anesthetics. (A) LFP (top panel) and spiking data (bottom) recorded by multi-electrode array implanted into a human patient’s temporal cortex. Slow oscillations (<1 Hz) visible in the LFP correspond to an alternation between transients of high and low firing rate, i.e. UP and DOWN state dynamics, evident in the spiking activity (gray: UP state detection based on population spike count, see Methods). (B) UP state duration against previous DOWN state duration, showing a clear negative correlation. (C) Bar plot of Pearson correlation $C(D_{n+k}, U_n)$ as a function of lag $k$. Two standard deviations of the Pearson correlations when shuffling state durations (dashed lines) provide an interval of confidence outside of which empirical correlations may be considered non-trivial. The same analyses are reported for other species during sleep and anesthesia: sleep in the monkey premotor cortex (D) and in the rat pre-frontal cortex (E), anesthesia in the monkey (G) and rat V1 (H). Panels (F) and (I) report the lag-correlation during sleep and anesthesia in the rat.

correlations remain between DOWN and UP states lag $k$ remains significantly negative up to a separation on the order of five UP/DOWN cycles in sleep data. In contrast, the correlations at lag $k$ decay to zero immediately after one UP/DOWN state cycle in anesthesia [Jercog et al., 2017]. Thus, the network retains a memory of previous cycles
significantly longer in SWS than anesthesia.

In order to investigate whether the correlation between UP-DOWN state duration and its memory through time are specific to brain states across species and regions of cortex, data from primary visual cortex of animals under different anesthetics (monkey under sufentanil, rat under ketamine and medetomidine), and several animals sleeping (human temporal cortex, monkey premotor cortex, and rat prefrontal cortex) were analyzed.

The results of these analyses are reported in Fig.1 where in panels D-I we show the scatter plot of DOWN against following UP state duration. In all the sleep recordings a banana-shaped distribution is observed, indicating a robust negative UP-DOWN state correlation (for sleeping rats, 5/5 of animals analyzed showed a negative correlation, both before and after a navigation task).

Conversely, in anesthetized recordings the results are consistent with previously published results [Jercog et al., 2017], an either positive or non-significant correlation is recorded (for anesthetized monkeys, 5/6 recordings presented a significant correlation and 1/6 a non-significant correlation; for anesthetized rats, 4/7 animals showed a significant positive correlation, 2/7 showed a positive non-significant correlation and the remaining 1/7 showed a negative significant correlation.)

Moreover, comparing within the same species (Fig.1F, I), the lag-correlation is verified to be different between sleep and anesthesia (we compare here the same species for the sake of coherence), with a much longer memory during sleep.

These observations demonstrate a clear difference in the correlation structure of the network dynamics during sleep and anesthesia, revealing fundamental differences in the dynamical mechanisms determining UP-DOWN state activity.

**Existing spiking network model reproduces anesthesia- but not sleep-like slow waves**

In order to investigate the mechanisms behind the UP and DOWN state duration correlations, we use a network of spiking neurons with conductance-based (COBA) synapses. The network is composed of 80% RS (regular spiking) excitatory and 20% fast spiking (FS) inhibitory neurons. Every neuron is modeled as an Adaptive Exponential integrate-and-fire cell (AdExp) [Brette and Gerstner, 2005]. In the absence of adaptation, the system is characterized by two stable states: a near-silent state (DOWN state) and a relatively high-activity state (UP state).

To allow for transitions between the two states, every neuron receives an independent identically distributed (i.i.d.) zero-mean noise of amplitude $\sigma$ that permits a jump from the DOWN to the UP state. The presence of spike-frequency adaptation of strength $b$ (see Methods) for RS neurons [Pospischil et al., 2008] allows the system to transition back to the DOWN state. Indeed, in RS neurons adaptation builds up as they spike, i.e.
during UP states, and consequently reduces the firing rate of the excitatory population, which can cause the transition to a DOWN state. Adaptation decays exponentially throughout time when the neuron is silent, for instance during DOWN states (see Methods for equations).

![Figure 2](image)

**Figure 2: Enhanced noise sensitivity in inhibitory neurons as a mechanism for prolonged UP states.** (A) Firing rate of isolated E (regular-spiking, blue), I cells (fast-spiking, red) cells as a function of input noise amplitude, and ersatz I cells with the same single-cell parameters as E cells (see Supplementary Table 1 for values) and zero adaptation, such that the gain is similar to that of E cells (red, dotted). Inhibitory cells are observed to have a higher gain at high noise amplitude values. (B) Time taken to reach peak adaptation value in UP state against mean ratio of E to I firing rate at the onset of UP states for varying amplitude of external noise (error bar: standard error of the mean). (C) Histogram of UP state duration for E/I ration in different intervals (different colors). UP states can reach longer durations for low E/I ratio. Statistics gathered for UP states over simulations with different values of noise amplitude (46 \( \sigma < 52 \) pA). (D) Mean UP and DOWN state duration vs amplitude of external noise (shaded: standard error of the mean), for low (\( b = 10 \) nS, left) and high (\( b = 50 \) nS, right) adaptation strength in the spiking network model (see text and Methods).

Such mechanisms for the emergence of UP and DOWN state dynamics has been so far established in the literature (see e.g. [Jercog et al., 2017, Holcman and Tsodyks, 2006]). We observed the same mechanism in a spiking network model of Adaptive integrate and fire neurons with voltage-dependent synapses and a different gain between excitatory and inhibitory cells. The network dynamics is characterised by an alternation between UP and DOWN states whose durations follow an exponential distribution, in accordance with experimental data (see Fig 1C for data and Supplementary material for the model). For a fixed value of noise amplitude \( \sigma \) we observe a positive correlation between UP-DOWN durations, where the adaptation strength \( b \) changes the UP and DOWN state length, with no obvious effect on their correlation. The correlation between UP and
Figure 3: Interplay between spike-frequency adaptation strength and noise amplitude allows for a transition from sleep-like to anesthesia-like slow waves in a spiking network model. (A) UP state duration against previous DOWN state duration for external noise amplitude varying throughout time in the range \([-\Delta, \Delta]\). Here, \(\Delta = 3\) pA, showing negatively correlated (\(r = -0.15, p << 0.001\)), 'sleep-like' durations for low adaptation (\(b = 10\) nS, left) and uncorrelated (\(r = -0.01, p > 0.05\)), 'anesthesia-like' durations for high adaptation (\(b = 50\) nS, right). Inset left: replacing I cells with 'ersatz inhibitory' cells endowed with the same physiological properties as E cells (sodium sharpness and leakage reversal, see Supplementary Table 1 for values) such that the gain is similar to that of E cells (see Fig. 2A, dashed line). UP state durations are reduced and the negative correlation vanishes (\(r = , p > 0.05\)). Inset right: sketch of noise time course, in which different colors represent different noise amplitude \(\sigma\). (B) Variation of next UP to previous DOWN state correlation as a function of adaptation strength, for different ranges \(\Delta\) of noise fluctuation (markers: significant correlations, dashed lines: confidence interval obtained by shuffling, see Methods).

DOWN state duration remains positive or non-significant over the all range of \(b\) values here investigated. This is consistent with adaptation having decayed after long DOWN states: following noise-triggered onset, the following UP state displays a high rate of activity that may sustain a long UP state. Consequently, long DOWN states tend to be followed by long UP states, hence the positive correlation. Exploring the parameter space by varying other parameters such as neurons’ excitability or synapses’ quantal conductances, positive or non-significant correlations were also always obtained.

In accordance with previously reported results [Jercog et al., 2017], the model dis-
cussed so far is suitable for UP-DOWN dynamics during anesthesia but not for sleep, where we have shown a clear and robust inverse relationship. This shows additional elements are needed to accurately model the empirical UP-DOWN state dynamics during sleep.

**High inhibitory neuron gain and adaptation gating of fluctuations needed for switching between anesthesia-like and sleep-like dynamics**

In order to investigate mechanisms entering into play during sleep we observe that, additionally to adaptation strength, another natural parameter for affecting UP-DOWN state duration is the amount of noise \( \sigma \). The role of external noise in our system is complex as noise affects excitatory and inhibitory cells differently, thus rendering the collective scenario non-trivial. In fact, in Fig. 2A isolated inhibitory FS cells are shown to have a higher gain in their response to external noise amplitude \( \sigma \) with respect to excitatory RS cells. As a result, we expect that the higher the noise amplitude \( \sigma \), the lower the ratio of excitatory to inhibitory activity (E/I ratio). In fact, by performing network simulations with varying \( \sigma \) we observe that the E/I ratio at the onset of UP states (where adaptation has not yet built up such that dynamics are noise-driven) decreases with \( \sigma \) (Fig. 2B). This effect has crucial consequences on population dynamics in terms of UP state duration. In fact, as shown in Fig. 2C, UP state duration is enhanced and can reach especially high values for low E/I ratio. In particular, for low E/I ratio large inhibition slows the increase of excitatory activity at the onset of UP states. Therefore decreasing the E/I ratio at UP state onset results in decelerating subsequent adaptation build throughout the UP state, which can be quantified the time taken before the maximum value of adaptation is reached in each UP state (Fig. 2B), thus permitting longer UP states. As a result, high noise amplitude \( \sigma \) implies long UP states as reported in simulation results (Fig.2D). In our model, UP to DOWN transitions are driven by deterministic adaptation build-up rather than by stochastic noise fluctuations. Therefore, due to the higher gain of inhibitory FS cells, the higher the noise amplitude the longer UP states can be. Additionally, since increased noise amplitude causes larger fluctuations more likely to occasion DOWN to UP transitions, the higher the noise amplitude the shorter DOWN states tend to be. This implies that UP and DOWN state durations vary in an anti-correlated fashion with noise amplitude \( \sigma \). In other terms, if \( \sigma \) were to vary throughout time, a negative correlation could be observed between consecutive DOWN and UP state durations.

To account for correlation inversion in our model, we introduce a parameter, \( \Delta \), describing the variability of noise amplitude \( \sigma \) throughout time. Here, the noise \( \sigma \) takes successive values within a range \( \Delta \) of amplitudes \( \sigma \) (see Methods), where each value is held constant over a time interval of duration \( T \) (inset of Fig.3A, right). It should be noted
that the resulting UP and DOWN duration correlations do not depend on the specific choice of $T$, as far as it is long enough to contain a sufficient number of UP-DOWN transitions in order to obtain well-defined UP DOWN statistics (in the plots shown in Fig 3 $T = 100s$).

By introducing variation of noise amplitude in time, a banana shape is observed in the scatter plot of UP and DOWN state duration (see Fig.3A, left). Accordingly, a negative correlation between UP and DOWN state durations emerges increasing the range $\Delta$ of variation of the noise amplitude $\sigma$. In order to further investigate the mechanism based on a higher gain of inhibitory FS cells, we performed a simulation in a set-up where excitatory and inhibitory neurons have similar gains (see red dashed line in new Fig.2A). We demonstrate that negative correlation between DOWN and next UP state durations require a higher gain on FS-I cells in the model. This is simulated by endowing both E and I cells with RS properties (sodium sharpness and leakage reversal, see Supplementary Table 1 for parameter values) hence lowering the gain of I cells to match that of E cells, while keeping all other parameters identical to those used to produce Fig 2AB, left. As shown below on the left panel, this yields consistently shorter UP states for all noise amplitudes (green), confirming the role played by FS-I cells in sustaining UP states. Moreover, in this condition DOWN and next UP state durations are found to be uncorrelated (right panel, Pearson correlation $r = 0.03$, $p = 0.5$), which confirms that higher FS gain is a necessary mechanism to obtain sleep-like negative correlation by varying noise amplitude (Fig. 3A inset, right).

Additionally, a fundamental role for the emergence of sleep-like negative correlation is played by spike frequency adaptation. Indeed, the inverse correlation disappears as the adaptation strength $b$ is increased (Fig. 3B). Accordingly, a negative correlation between UP and DOWN state durations emerges increasing the range $\Delta$ of variation of the noise amplitude $\sigma$. Moreover, for sufficiently high $\Delta$, an increase in the adaptation strength $b$ is able to induce a transition from negative (sleep-like) to positive (anesthesia-like) correlation. In other words, adaptation is able to filter out noise variability, thus determining a positive correlation.

Apparent in the scatter plots of panel 3B, when adaptation is low, various values of noise amplitude $\sigma$ (indicated by colors) cluster together in the scatter plot, altogether yielding a banana shape. Conversely, for high adaptation strength, data representing different values of noise amplitude overlap in the scatter plot, resulting in a non-significant or positive correlation. This can be understood as strong adaptation limiting the duration of UP states (green line in Fig. 3A, right), even in the presence of strong noise, and more generally controlling the transitions between UP and DOWN states. In sum, the model highlights the dominant mechanisms at work in each brain state, with the system being strongly adaptation driven in anesthesia, and more fluctuation driven in sleep.

To investigate functional consequences of this difference in neuromodulation between
sleep and anesthesia, we perform simulations to evaluate to what extent a stimulus affects collective dynamics. As shown in Fig. 4, the stimulus is simulated by delivering a spike train with Poisson statistics to all neurons, and the spike count after the stimulation is compared in the presence and in the absence of the stimulus (see Methods). Immediately after stimulation, the anesthesia-like network is more responsive: as higher adaptation makes the network more silent, more spikes are evoked by the stimulus, relative to spontaneous firing rates. However, in the sleep-like network the difference between stimulated and non-stimulated dynamics diverges significantly faster, as lower adaptation makes the dynamics more sensitive to a stimulus. After tens of seconds, we therefore find that the difference between stimulated and non-stimulated networks is larger for low adaptation strength, suggesting a more sustained response to the stimulus in the sleep-like case. The findings suggest that low adaptation strength renders sleep-like networks more sensitive to perturbations, thus allowing enhanced capacity for encoding than in anesthesia-like networks.

The findings indicate that higher gain for inhibitory than excitatory neurons is a necessary mechanism to model sleep-like slow waves. Transitions from sleep-like to anesthesia-like dynamics can be accounted for by increasing adaptation strength which filters out fluctuations and perturbations. Therefore, the model predicts that anesthesia slow-waves are less sensitive to fluctuations and therefore more stationary than sleep slow waves, and that enhancing cholinergic neuromodulation to decrease adaptation can lead to a change in slow wave type.

**Enhanced stationarity in anesthesia compared to sleep slow waves consistent with model prediction**

A crucial ingredient of our model is the variability $\Delta$ in noise amplitude, especially in the sleep-like regime. Indeed, for lower adaptation strength, such as in SWS, noise fluctuations may play a larger role in shaping UP-DOWN dynamics. Accordingly, we expect to observe a higher variability in UP and DOWN state durations (as a direct outcome of noise variability, see Fig. 1) during sleep with respect to anesthesia. Comparing the mean empirical values of UP and DOWN state durations over relatively long time windows of 100 UP-DOWN cycles (i.e. $10^2$ s), we observe a higher variability, of the order of 200%, under sleep as compared to under anesthesia, as predicted by the model (see Methods). To further characterize the time scale of noise fluctuations, the time window size was varied, and the correlations across windows were studied. By collecting UP and DOWN durations in each window during sleep, we observe that, just as in our model, UP-DOWN state durations belonging to different windows have different correlation values. For short time windows (up to the order of 50 cycles), the Pearson coefficient is positive in the majority of windows, but becomes negative when computed over longer windows...
Figure 4: Higher sensitivity to perturbations in sleep-like versus anesthesia-like networks. (A) A stimulus is delivered during an UP state to all neurons in the network (upper panel) and the dynamics is compared to the system without stimulation (lower panel). (B) Absolute difference between population spike counts over time in stimulated and non-stimulated networks, normalised by non-stimulated mean spike count, for two values of adaptation strength $b$, averaged over trials (shaded area: error in the mean over all trials, see Methods). (C) Linear regression slope for all trials, for the two different values of adaptation strength (error bars: error of the mean over all trials). The slope is significantly larger (independent Student’s T-test, $p = 0.03$) for lower adaptation, denoting less stable dynamics and increased capacity for sustained stimulus encoding in the sleep-like case.
(see Supplementary Material). This suggests that fluctuations take place at a time scale $T$ that can be as fast as the order of 10 seconds. It is important to note, at this point, that our analyses are performed on relatively long recordings (from 20 minutes to several hours), and therefore one could assume that the properties of the system may change throughout the time of the recordings. The time scale $T$ over which such changes occur, however, is relatively slow as compared to that of UP-DOWN dynamics ($\sim 1$ s), i.e. in the range of tens of seconds. This confirms the previous assumption that the time scale $T$ of fluctuations is longer than the UP-DOWN cycle duration (of the order of 1 second). Conversely, $T$ is much shorter than the duration of all our recordings (12 minutes to 3 hours) for either sleep or anesthesia, such that the absence of a negative correlation during anesthesia cannot be explained by too short recordings (unless $T$ in anesthesia is not the same as in sleep, but much longer than the duration of the recordings studied here).

Additionally, background fluctuations at time scale $T$ are present during sleep but absent during anesthesia, consistent with the apparent long memory of the UP-DOWN state duration correlation in SWS. Indeed, one may consider a period of time $T$ over which background noise may be approximated as constant. During low noise amplitude periods, UP states are long and DOWN states short; during high noise amplitude periods, UP states are short and DOWN states long. Independent of the lag, UP state durations undere negatively correlated to DOWN state durations proximal in time, provided that they occur within the same period of duration $T$. It is verified that the order of magnitude of $T$ matches that of the time scale of the memory in sleep (order of 10 UP-DOWN cycles, Fig. 1C, F, I).

**Increasing cholinergic modulation in vitro causes transition from anesthesia- to sleep-like dynamics**

Another prediction of our model is the ability of adaptation strength to modulate the correlations in UP and DOWN state durations. Spike-frequency adaptation simulates an effective action of activity-dependent potassium conductances, physiologically affected by neuromodulators [McCormick and Williamson, 1989]. It has been observed that neuromodulation is depressed during anesthesia [Jones, 2003], and thus the strength of adaptation should be increased [McCormick and Williamson, 1989]. This is consistent with our model prediction, where a transition to anesthesia (higher adaptation) yields a positive correlation between UP and DOWN states.

We therefore conducted an experiment to directly validate our prediction. To this purpose we performed extracellular recordings of neural activity in acute slices of entorhinal cortex from wild type juvenile mice. A great advantage of in vitro preparations is the possibility to pharmacologically modulate adaptation [McCormick and Williamson, 1989]
Figure 5: Reducing adaptation by addition of carbachol in mouse slice preparations produces a transition from anesthesia-like to sleep-like dynamics (A) Illustration of a horizontal mouse brain slice. Extracellular recording pipettes for Multi-Unit Activity (MUA) were placed in layer 2/3 of the entorhinal cortex. (B) MUA throughout time, recorded for different carbachol concentrations c for an example slice (shaded: UP state detection). UP state frequency is observed to increase with carbachol concentration. (C) For the same example slice, UP state against previous DOWN state duration for different carbachol concentrations, showing a positive correlation ($r = 0.64, p < 0.05$) in the control condition ($c = 0 \mu M$), non-correlated for an intermediary concentration ($c = 0.025 \mu M, r = 0.00$), and a negative correlation ($c = 0.05 \mu M, r = -0.37, p < 0.05$) when the highest carbachol concentration is added. (D) For all recorded slices, correlation between UP state and previous DOWN state duration as a function of carbachol concentration. Consistent with model predictions on the effect of adaptation strength, all slices exhibit a positive or non-significant, ‘anesthesia-like’ correlation in the control condition ($c = 0 \mu M$) and a negative, ‘sleep-like’ correlation for the highest carbachol concentration ($c = 0.05 \mu M$), when adaptation is blocked (markers: significant correlations, colors: different slices, dashed lines: shuffles, see Methods).
by dissolving neuromodulators in the artificial cerebrospinal fluid (ACSF) in which the slice is recorded. To cause an effective decrease of adaptation strength, carbachol, an agonist of both nicotinic and muscarinic acetylcholine (ACh) receptors is used [McCormick and Williamson, 1989]. By increasing concentrations of carbachol (0, 0.025, 0.05 µM), we observe lengthening UP states and shortening DOWN states, Fig. 5, in accordance with a lower amount of spike-frequency adaptation, as in the model. Importantly, we report a clear tendency to more negatively correlated, sleep-like UP and DOWN states durations at higher carbachol concentrations.

In summary, the in vitro manipulations using cholinergic agonist carbachol support the model prediction by which decrease of adaptation strength permits a transition from anesthesia-like to sleep-like slow waves.

**Discussion**

In the present paper, we have shown two types of slow waves by analyzing multi-electrode extracellular recordings in human and animal cerebral cortex. This conclusion was reached based on the temporal patterns of UP and DOWN states, an alternation of which causes slow waves to emerge. A first type of slow waves shows positively correlated consecutive UP and DOWN states and has been found in previous work [Jercog et al., 2017]. Here we report a second type of slow waves displaying negatively correlated UP and DOWN states that remain correlated across longer distances in time. Further, we report that the first type of slow waves is more pervasive in anesthetized states, while the second type prevails during natural slow-wave sleep. Using computational models, we show that longer UP states correspond to conditions with diminished adaptation, higher noise amplitude, and higher gain on inhibitory than excitatory cells. In contrast, longer DOWN states can be obtained through increasing adaptation and decreasing noise. In summary, our simulations and experiments demonstrate a cholinergic switch between the two types of slow waves distinguished for the first time, to our knowledge, here. We further show that the two types of slow waves differ in their sensitivity to external inputs, demonstrating that perturbations to networks in anaesthetized type-1 networks are less effective than perturbations in slow wave sleep type-2 networks.

Specifically, a larger effect of noise fluctuations on network dynamics is observed during sleep, yielding a negative, long-memory correlation between UP and DOWN state durations. Conversely, during anesthesia the dynamics is more stable and characterized by short-memory and positive correlation between state durations. Employing a spiking neuron network model revealed that, during anesthesia, fluctuations are filtered out by the modulatory effect of spike-frequency adaptation, and hence produce much smaller effects on collective dynamics. Cholinergic neuromodulators are known to control spike-frequency adaptation, although other neuromodulators also affect adaptation as well as
neural conductance and noise sensitivity [McCormick, 1992], which are beyond the scope of this paper. The adaptation-gating based mechanism is demonstrated by modulation of spike-frequency adaptation strength in acute cortical slices. Indeed, addition of carbachol, a cholinergic receptor agonist, induces a switch from anesthesia-like to sleep-like slow waves. For the sake of simplicity, external noise was chosen to be the only effective source of variability in the model. Nevertheless, this is not the only possible choice: one could also consider variability in other parameters in time, that can be tuned to produce longer UP states and shorter DOWN states, like inhibitory conductance [Sanchez-Vives et al., 2010] or even adaptation strength (Fig. 4E). In sum, adaptation filters out the effects of time variation of the system’s parameters, in anesthesia but not in sleep.

In addition, we show the implications of a switch in slow wave type for the network’s coding properties, with sleep-like slow waves associated with higher sensitivity to stimuli and greater capacity for encoding information in a sustained manner. This may help explain why key cognitive processes, such as memory consolidation, can take place during sleep [Wilson and McNaughton, 1994, Mehta, 2007, Peyrache et al., 2009], while anesthesia causes amnesia and memory impairment [Culley et al., 2003, Rudolph and Antkowiak, 2004, Timofeev and Chauvette, 2018]. Our observation of two types of slow-waves suggests that the temporal characteristics of slow-wave dynamics reported here may help explain cognitive differences between anesthetized and sleeping states. For example for memory consolidation to occur, the neocortex should encode information by changing its dynamics upon receiving signals from the senses as well as subcortical regions and the hippocampus. This implies that a non-trivial change in external input should be able to modulate the statistics of cortical activity. We showed (Fig. 4) that in models of anesthesia, unlike in models of sleep, strong adaptation filters out the effects of perturbations on UP-DOWN state dynamics, so that any information encoded in the amplitude of inputs to the neural assembly does not affect the network dynamics, and consequently will not be encoded.

The fact that larger gain of inhibitory cells was necessary to obtain sleep-like dynamics in our model is consistent with experimental findings that inhibitory firing rate rises faster than excitatory firing rate upon injecting input current to cells [Nowak et al., 2003, Contreras and Palmer, 2003]. The higher gain has also been reported to be crucial for reproducing other empirical observations in recent modelling work. In particular, inhibitory cells were endowed with enhanced gain to simulate excitatory and inhibitory firing rates at the onset of UP and DOWN states under anesthesia [Jercog et al., 2017]. Additionally, a gain difference between excitatory and inhibitory cells was also needed to model network dynamics and responsiveness to multiple interacting stimuli in the awake state [Chemla et al., 2019].

Our results may also be considered in the light of intracellular dynamical differences between anesthesia and natural sleep, as investigated with ketamine-xylazine anesthesia
in cats [Chauvette et al., 2011] and mice [Urbain et al., 2019]. While the former provides evidence for reduced depolarization, lower slow wave amplitude and longer DOWN states, consistent with stronger adaptation in anesthesia than sleep, the latter reports increased depolarization in anesthesia as compared to sleep, and enhanced synchrony between thalamus and cortical slow waves. By comparing different species, brain regions, and anesthetics, we highlight that despite variations across recordings of the depolarization and subsequent absolute duration of DOWN and UP states, a pattern is robustly followed in terms of correlation between the duration of consecutive states for all experimental conditions studied here. At the opposite end of the spatial scale, it may also be useful to inspect the results in comparison to macroscopic studies having compared activation patterns across brain regions in sleep and anesthesia [Brown et al., 2010, Akeju and Brown, 2017, Urbain et al., 2019, Chauvette et al., 2011]. Indeed we provide a possible mechanistic explanation, based on filtering of information transfer between neural assemblies by adaptation, which could lead to differential communication between brain regions during sleep and anesthesia at the macroscopic scale.

One should note that stronger fluctuations in slow wave dynamics observed during sleep than anesthesia, at a period around several seconds to tens of seconds (slower than UP-DOWN cycles), are consistent with previous results in electroencephalography reporting an alternation between distinct oscillatory patterns at a similar time scale of tens of seconds, with autonomic and motor correlates [Parrino et al., 2012]. Sources of fluctuations in sleep slow waves within the brain may originate outside neocortex as hippocampal inputs are known to modulate neocortical UP and DOWN state dynamics [Battaglia et al., 2004], as well as midbrain reticular neurons that discharge with period around 18s [Steriade et al., 1982], and thalamic spindles with period 5s [Nicolas et al., 1997].

Finally, we emphasize that understanding the role of adaptation in filtering out external variability may shed light on pathological conditions. Indeed, slow oscillations are a hallmark of pathological unconscious states, found in severely brain injured patients and vegetative state patients [Sanchez-Vives et al., 2017]. In such patients, disruption of causality and complexity in response to transcranial magnetic stimulation [Rosanova et al., 2018] appears consistent with anesthesia-type slow waves, suggesting adaptation-like mechanisms could play a critical role in impairing information representation. Furthermore, deceleration of slow oscillatory patterns during SWS [Mander et al., 2016, Castano-Prat et al., 2017] and loss of memory [Prinz et al., 1982] are also biomarkers of Alzheimer’s disease. The cholinergic system, that modulates spike-frequency adaptation [McCormick and Williamson, 1989], also breaks down in Alzheimer’s disease [Kihara and Shimohama, 2004]. Our results therefore suggest that the loss of acetylcholine in Alzheimer’s disease should increase spike-frequency adaptation, similarly to under anesthesia. It is therefore conceivable that the neocortex of Alzheimer’s patients can-
not encode fluctuating inputs from the hippocampus during sleep due to anesthesia-like slow-wave dynamics. This mechanism may contribute to explaining why new memories cannot be formed, and to better comprehending how treatments restoring acetylcholine levels alleviate Alzheimer’s sleep and memory symptoms [Babiloni et al., 2013]. Our study directly predicts that the anesthesia-type slow-wave dynamics should be observed in Alzheimer’s patients during their natural sleep, and provides an approach to modulating and quantifying the restoration of sleep type slow waves, perhaps a fruitful direction to explore in the design of new therapies.

Figure S1: UP DOWN state statistics in experimental data. (A-D) Slow-wave sleep data from human temporal cortex. (A-B) Both UP and DOWN state durations follow exponential long-tailed, distributions. (C-D) Averaged population firing rate, aligned to UP state onset, after short (C) or long (D) DOWN state durations. UP states following very long DOWN states, > 0.8s, are always short, while UP states following the shortest DOWN states, < 0.3s, can be up to around three times longer. (E) Mean UP and DOWN state durations in 100 UP-DOWN-cycle windows in time, normalized by the mean duration over the whole recording, highlight larger fluctuations across windows in sleep (human data, left) than anesthesia (rat data, right). The mean in each window is represented by a full line, while the standard error of the mean is represented by the shaded area.
Figure S2: UP and DOWN states in adaptive exponential integrate-and-fire model. (A) Spikes and population activity produced by a spiking model of a RS (blue)-FS (red) neuron network with spike-frequency adaptation on RS cells (blue, dashed line) exhibit UP-DOWN state dynamics (gray: UP state detection). (B) UP and DOWN state durations are exponentially distributed, consistently with empirical data in both sleep and anesthesia. (C) UP state against previous DOWN state durations yield a significant positive correlation ($r = 0.16, p < 0.05$) in this example simulation. (D) State durations in different simulations with increasing adaptation strength, showing shortening UP states and lengthening DOWN states (full line: mean, shaded area: standard error in mean). (E) Modeled UP to previous DOWN state duration correlation against adaptation strength reveals systematic positive or non-significant correlations and indicates an increase of the correlation with adaptation level (markers: significant correlations, shaded: interval of confidence obtained by shuffling). This is therefore a good model for anesthesia, but not deep sleep.
